Abstract

Constitutive equations are derived for the viscoelastoplastic response of amorphous glassy polymers at isothermal loading with small strains. A polymer is treated as an ensemble of cooperatively relaxing regions (CRR) which rearrange at random times as they are thermally agitated. Rearrangement of CRRs reflects the viscoelastic response of the bulk medium. At low stresses, CRRs are connected with each other, which implies that the macro-strain in a specimen coincides with micro-strains in individual relaxing regions. When the average stress exceeds some threshold level, links between CRRs break and relaxing domains begin to slide one with respect to another. Sliding of micro-domains is associated with the viscoplastic behavior of polymers. Kinetic equations are proposed for viscoplastic strains and for the evolution of the threshold stress. These equations are validated by comparison with experimental data in tensile relaxation tests and in tests with constant strain rates. Fair agreement is demonstrated between results of numerical simulation and observations for a polyurethane resin and poly(methyl methacrylate).

Key-words: Glassy polymers, Polyurethane, Poly(methyl methacrylate), Viscoelasticity, Viscoplasticity

1 Introduction

A constitutive model is derived for the viscoelastoplastic response of amorphous glassy polymers at isothermal loading with small strains. The time-dependent behavior of glassy polymers has become the focus of attention in the past decade [1]–[20]. This may be explained by the use of new experimental techniques which allow complicated time-dependent programs of loading to be carried out (loading and unloading with different strain rates interrupted by relaxation and superposition of small oscillatory strains on loading with constant strain rates) at various temperatures.

The present study is concerned with the response of polymers in relaxation tests and in tests with constant strain rates. We confine ourselves to relatively slow programs of loading and to temperatures in the sub- T_g region, where T_g is the glass transition temperature. This implies that crazing and other phenomena associated with brittle fracture are excluded from our consideration, which focuses on the sub-yield and post-yield response of ductile polymers. To simplify the analysis, we deal with uniaxial loading at small strains. These limitations may be avoided by using conventional approaches, see, e.g., [21], but we do not dwell on this issue. The purpose is to develop a constitutive model which describes the viscoelastic and viscoplastic response of amorphous polymers at the micro-level, on the one hand, and which is sufficiently

simple to be used in the study of three-dimensional deformations of polymers with complicated geometry, on the other. We aim to design stress-strain relations which correctly predict two phenomena observed in experiments: (i) changes in elastic moduli and relaxation spectra induced by changes in the test's temperature and (ii) the influence of the strain rate and temperature on the apparent yield stress.

To describe the viscoelastic response of glassy polymers, we employ the concept of cooperative relaxation [22]. An amorphous polymer is treated as an ensemble of cooperatively rearranging regions (CRR). Any CRR is modeled as a globule consisting of scores of neighboring strands of long chains which change their position simultaneously because of large-angle reorientation of strands [23, 24]. The characteristic length of a relaxing region amounts to several nanometers [25]. In the phase space, a CRR is treated as a point trapped in its potential well on the energy landscape. A CRR spends most time at the bottom level of its trap. At random times, it hops to higher energy levels being thermally agitated. We adopt the transition-state theory [26] which postulates that some liquid-like (reference) level exists on the energy landscape. When a CRR reaches this reference state in a hop, it totally relaxes. Viscoelasticity of a glassy polymer is modeled as sequential rearrangements of CRRs trapped in potential wells with various depths.

CRRs are assumed to be connected with one another by some links (which model temporary crosslinks, entanglements and van der Waals forces). At relatively low stresses, the links prevent mutual displacements of CRRs, which implies that the micro-strains in relaxing regions coincide with the macro-strain in a specimen. When the average stress in an ensemble of CRRs exceeds some threshold value, links between CRRs break, and relaxing regions become (partially) free to change their positions with respect to each other. The mutual displacement of CRRs models the viscoplastic deformation at the micro-level.

The exposition is organized as follows. Thermally induced rearrangement of CRRs is discussed in Section 2. Section 3 deals with constitutive relations for the viscoelastic behavior of an amorphous polymer. Kinetic equations for the evolution of the threshold stress are proposed in Section 4. Section 5 is concerned with comparison between experimental data and results of numerical simulation. Some concluding remarks are formulated in Section 6.

2 Kinetics of rearrangement

The position of the liquid-like state at the glass transition temperature T_g is accepted as the zero energy level on the energy landscape. The depth of a potential well where a CRR is trapped with respect to the zero energy level is denoted as $w \geq 0$. We suppose that the position of the reference state on the energy landscape may change with temperature and denote by $\Omega(T)$ its ascent at some temperature $T < T_g$ with respect to the position of the reference level at T_g (the function $\Omega(T)$ satisfies the natural condition $\Omega(T_g) = 0$).

Denote by X_0 the concentration of traps per unit mass of the bulk medium. For simplicity, X_0 is assumed to be a constant (independent of temperature and the loading history). Rearrangement of relaxing regions is entirely characterized by the function $X(t, \tau, w)$ which equals the concentration of CRRs (per unit mass at time t) trapped in cages with potential energy w which have last rearranged before instant $\tau \leq t$. The current distribution of traps is described by the probability density, $p(t, w)$, of traps with energy w at time t . The functions $p(t, w)$ and $X(t, \tau, w)$ are connected by the formula

$$p(t, w) = \frac{X(t, t, w)}{X_0}. \quad (1)$$

In the sequel, we confine ourselves to equilibrated polymers with steady-state distribution of

traps. This means that the function p is independent of time. Bearing in mind that in the sub- T_g region, the distribution of traps with various energies drastically depends on temperature T , we set $p = p(T, w)$.

Let $q(\omega)d\omega$ be the probability for a CRR to reach (in a hop) the energy level that exceeds the bottom level of its cage by some value ω' located in the interval $[\omega, \omega + d\omega]$. Referring to [27], we set

$$q(\omega) = \alpha \exp(-\alpha\omega),$$

where α is a material constant. The probability to reach the reference state in an arbitrary hop for a polymer equilibrated at a temperature T reads

$$Q(T, w) = \int_{w+\Omega(T)}^{\infty} q(\omega)d\omega = \exp\left[-\alpha(w + \Omega(T))\right].$$

Denote by $\Gamma_0 = \Gamma_0(T)$ the attempt rate (the average number of hops in a trap per unit time). The rate of rearrangement R equals the product of the attempt rate Γ_0 by the probability of reaching the reference state in a hop Q ,

$$R(T, w) = \Gamma(T) \exp(-\alpha w), \quad (2)$$

where the relaxation rate $\Gamma(T)$ is given by

$$\Gamma(T) = \Gamma_0(T) \exp\left[-\alpha\Omega(T)\right]. \quad (3)$$

Equating the relative rates of rearrangement to the function R , we arrive at the differential equations

$$\frac{1}{X(t, 0, w)} \frac{\partial X}{\partial t}(t, 0, w) = -R(T, w), \quad \left[\frac{\partial X}{\partial \tau}(t, \tau, w) \right]^{-1} \frac{\partial^2 X}{\partial t \partial \tau}(t, \tau, w) = -R(T, w). \quad (4)$$

The solutions of Eq. (4) with the initial condition $X(0, 0, w) = X_0 p(T, w)$ [see Eq. (1)] read

$$\begin{aligned} X(t, 0, w) &= X_0 p(T, w) \exp\left[-R(T, w)t\right], \\ \frac{\partial X}{\partial \tau}(t, \tau, w) &= X_0 F(\tau, w) \exp\left[-R(T, w)(t - \tau)\right], \end{aligned} \quad (5)$$

where

$$F(\tau, w) = \frac{1}{X_0} \frac{\partial X}{\partial \tau}(t, \tau, w) \Big|_{t=\tau}.$$

The number $N(t, w)$ of relaxing regions (per unit mass) in traps with potential energy w rearranged within the interval $[t, t + dt]$ equals the sum of the numbers of CRRs rearranged for the first time at instant t and those that have last rearranged at some instant $\tau \in [0, t]$ and reach the reference state at time t ,

$$N(t, w) = -\frac{\partial X}{\partial t}(t, 0, w) - \int_0^t \frac{\partial^2 X}{\partial t \partial \tau}(t, \tau, w) d\tau. \quad (6)$$

Neglecting the duration of a hop (a few picoseconds [23]) compared to the characteristic time of relaxation in the sub- T_g region, we find that $N(t, w)$ coincides with the number of CRRs landing within the interval $[t, t + dt]$ in traps with potential energy w ,

$$N(t, w) = X_0 F(t, w). \quad (7)$$

Substitution of Eqs. (4) to (6) into Eq. (7) results in the Volterra equation

$$F(t, w) = R(T, w) \left\{ p(T, w) \exp[-R(T, w)t] + \int_0^t F(\tau, w) \exp[-R(T, w)(t - \tau)] d\tau \right\}. \quad (8)$$

The solution of Eq. (8) is given by

$$F(t, w) = R(T, w)p(T, w),$$

which, together with Eq. (5) implies that

$$\frac{\partial X}{\partial \tau}(t, \tau, w) = X_0 R(T, w)p(T, w) \exp[-R(T, w)(t - \tau)]. \quad (9)$$

3 Constitutive equations

We assume that the macro-strain ϵ equals the sum of the viscoelastic strain ϵ_e and the viscoplastic strain ϵ_p ,

$$\epsilon(t) = \epsilon_e(t) + \epsilon_p(t). \quad (10)$$

The viscoelastic strain, ϵ_e , is the average strain in relaxing regions, and the viscoplastic strain, ϵ_p , is the average strain induced by displacement of CRRs one with respect to another. To simplify our analysis, we neglect the distribution of micro-strains and suppose that the micro-strain in any CRR coincides with ϵ_e .

A CRR is assumed to totally relax when it reaches the liquid-like state, which means that the natural (stress-free) configuration of a CRR after rearrangement coincides with the actual configuration of the bulk medium at the instant of rearrangement. For uniaxial deformation, the strain from the natural configuration of a relaxing region to its actual configuration at time t is given by

$$\varepsilon(t, \tau) = \epsilon_e(t) - \epsilon_e(\tau), \quad (11)$$

where $\tau \leq t$ is the last instant when the region was rearranged. A CRR is modeled as a linear elastic medium with the mechanical energy

$$\phi(t, \tau) = \frac{1}{2} c \varepsilon^2(t, \tau),$$

where $c = c(T)$ is the rigidity of a relaxing region. To minimize the number of material parameters in the constitutive equations, we assume the rigidity c to be constant and independent of the energy of trap w . Summing the mechanical energies of CRRs and neglecting the energy of their interaction, we find the strain energy density of a polymer (per unit mass)

$$\Phi(t) = \frac{1}{2} c \left[\varepsilon^2(t, 0) \int_0^\infty X(t, 0, w) dw + \int_0^t \varepsilon^2(t, \tau) d\tau \int_0^\infty \frac{\partial X}{\partial \tau}(t, \tau, w) dw \right].$$

Substitution of expressions (10) and (11) into this equality results in the formula

$$\begin{aligned} \Phi(t) = & \frac{1}{2} c \left[\left(\epsilon(t) - \epsilon_p(t) \right)^2 \int_0^\infty X(t, 0, w) dw \right. \\ & \left. + \int_0^t \left((\epsilon(t) - \epsilon(\tau)) - (\epsilon_p(t) - \epsilon_p(\tau)) \right)^2 d\tau \int_0^\infty \frac{\partial X}{\partial \tau}(t, \tau, w) dw \right]. \end{aligned} \quad (12)$$

At small strains, the average stress $\sigma(t)$ is expressed in terms of the macro-strain $\epsilon(t)$ by the conventional formula

$$\sigma(t) = \rho \frac{\partial \Phi(t)}{\partial \epsilon(t)}, \quad (13)$$

where ρ is mass density in the stress-free state. Combining Eqs. (12) and (13), we arrive at the stress-strain relation

$$\begin{aligned} \sigma(t) = & E_0(T) \left[\left(\epsilon(t) - \epsilon_p(t) \right) \int_0^\infty X(t, 0, w) dw \right. \\ & \left. + \int_0^t \left((\epsilon(t) - \epsilon(\tau)) - (\epsilon_p(t) - \epsilon_p(\tau)) \right) d\tau \int_0^\infty \frac{\partial X}{\partial \tau}(t, \tau, w) dw \right], \end{aligned} \quad (14)$$

where $E_0(T) = \rho c(T) X_0$ is the initial Young modulus.

To proceed with the analysis of Eq. (14), a concrete form of the distribution function $p(T, w)$ should be established. Referring to the random energy model [28], we assume that the probability density p is quasi-Gaussian,

$$p(T, w) = C(T) \exp \left[-\frac{(w - W(T))^2}{2\Sigma^2(T)} \right] \quad (w \geq 0), \quad P(T, w) = 0 \quad (w < 0), \quad (15)$$

where $W(T)$ and $\Sigma(T)$ are parameters of the Gaussian distribution and the constant C is found from the condition

$$\int_0^\infty p(T, w) dw = 1.$$

4 Kinetics of plastic flow

To describe the evolution of the plastic strain $\epsilon_p(t)$, we propose constitutive equations similar (to some extent) to the viscoplasticity theory based on overstress [29] (back stress [30]), see also recent publications [17, 18]. For simplicity, we confine ourselves to active loading with $\dot{\epsilon}(t) = d\epsilon(t)/dt \geq 0$, which means that the internal parameter λ (the material time associated with loading) may be set equal to the macro-strain ϵ . Our approach is based on the following hypotheses:

1. The level of plastic strain is determined by the threshold stress g which depends on temperature and the loading history.
2. Plastic deformation occurs only when the current average stress $\sigma(t)$ exceeds the threshold stress $g(t)$. The rate of change in the viscoplastic strain ϵ_p (with respect to the internal time λ) is proportional to the difference $\sigma - g$,

$$\frac{d\epsilon_p}{d\lambda} = K_1 \mathcal{H}(\sigma - g), \quad (16)$$

where K_1 is a material parameter and $\mathcal{H}(x)$ is the Heaviside function,

$$\mathcal{H}(x) = \begin{cases} 1, & x \geq 0, \\ 0, & x < 0. \end{cases}$$

3. For a stress-free material, the threshold stress has a fixed value g_0 . At the micro-level, g_0 determines the strength of links between CRRs which prevent their mutual displacements.

In the general case, the quantity g_0 depends on temperature T and on the strain rate $\dot{\epsilon}$ with which a specimen is loaded. A decrease in g_0 with temperature is explained within the framework of the theory of thermally activated processes: the growth of temperature implies an increase in the amplitude of thermal fluctuations, which reduces the strength of links between CRRs. The effect of strain rate is also quite natural provided that the links break according to the brittle pattern.

4. When the current stress σ exceeds the threshold stress, the quantity g changes. The rate of change in the threshold stress is determined by two mechanisms. The first is associated with a decrease in the current value of g caused by partial destruction of links between CRRs (we suppose that some distribution of the links' strength exists, and the links with low strengths break first). The rate of decrease in the threshold stress (with respect to the internal time λ) is assumed to be proportional to the difference $\sigma - g$. Bearing in mind that g is a nonnegative function, we set

$$\frac{dg}{d\lambda} = -K_2 g \mathcal{H}(\sigma - g), \quad (17)$$

where K_2 is a constant. Equation (17) ensures that $g(t) = 0$ for any $t \geq t_0$, provided that $g(t_0) = 0$.

5. The other mechanism for changes in the threshold stress g is associated with thermally induced healing of links between CRRs. We suppose that this process is similar to craze healing in glassy polymers, see [31] and the references therein. Because the healing process is driven by thermal fluctuations, its kinetics is analogous to that for the reformation process in a temporary network [32]. This means that the rate of reformation (per unit time t) for links between CRRs is proportional to the number of broken links,

$$\frac{dg}{dt} = K_3 \mathcal{H}(g_0 - g), \quad (18)$$

where K_3 is a constant.

6. In general, the parameters K_i ($i = 1, 2, 3$) depend on temperature T and the loading history. To reduce the number of adjustable parameters in the model, we assume that the effect of these factors is rather weak and treat K_i as material constants.

When λ coincides with the macro-strain ϵ , Eqs. (16) to (18) are transformed into the nonlinear differential equations

$$\frac{d\epsilon_p}{dt} = K_1 \mathcal{H}(\sigma - g) \frac{d\epsilon}{dt}, \quad \frac{dg}{dt} = K_3 \mathcal{H}(g_0 - g) - K_2 g \mathcal{H}(\sigma - g) \frac{d\epsilon}{dt} \quad (19)$$

with the initial conditions

$$\epsilon_p(0) = 0, \quad g(0) = g_0. \quad (20)$$

Given a loading program, $\epsilon(t)$, Eqs. (2), (14), (15), (19) and (20) uniquely determine the average stress $\sigma(t)$. The constitutive equations are determined by four functions of temperature, $E_0(T)$, $W(T)$, $\Sigma(T)$ and $\Gamma(T)$, one function of temperature and strain rate, $g_0(T, \dot{\epsilon})$, and three constants K_1 , K_2 and K_3 (without loss of generality, the parameter α in Eq. (2) may be set to unity). The total number of adjustable parameters in the model is essentially less than that in conventional stress-strain relations in viscoelastoplasticity based on the overstress concept [2, 17, 18].

5 Comparison with experimental data

To verify the constitutive equations, we determine adjustable parameters by fitting observations in tensile relaxation tests and in tensile tests with constant strain rates. We begin with the standard isothermal relaxation test with the loading program

$$\epsilon(t) = \begin{cases} 0, & t < 0, \\ \epsilon_0, & t > 0, \end{cases} \quad (21)$$

where ϵ_0 is a given strain (which is assumed not to exceed the yield strain). It follows from Eqs. (19) and (20) that

$$\epsilon_p(t) = 0, \quad g(t) = g_0(T, 0).$$

Substituting these expressions and Eqs. (2), (15) and (21) into Eq. (14), we find that

$$E(T, t) = C(T)E_0(T) \int_0^\infty \exp\left[-\left(\frac{(w - W(T))^2}{2\Sigma^2(T)} + \Gamma(T) \exp(-w)t\right)\right] dw,$$

where

$$E(T, t) = \frac{\sigma(t)}{\epsilon_0}$$

is the current Young modulus.

We begin with matching experimental data for a polyurethane resin ($T_g = 80^\circ\text{C}$). A description of specimens and the experimental procedure can be found in [33]. First, we fit observations in relaxation tests at various temperatures T . Given a parameter E_0 , the quantities W , Σ and Γ are found by using the steepest-descent algorithm. Afterwards, the initial Young modulus E_0 is determined by the least-squares technique.

Figure 1 demonstrates excellent agreement between experimental data and results of numerical simulation. The parameters W , Σ , E_0 and Γ are plotted versus the degree of supercooling $\Delta T = T_g - T$ in Figures 2 and 3. These figures show that far below the glass transition temperature, the quantities W , Σ , E_0 and Γ are fairly well approximated by the “linear” functions

$$W = a_0 + a_1\Delta T, \quad \Sigma = b_0 + b_1\Delta T, \quad E_0 = c_0 + c_1\Delta T, \quad \log \Gamma = d_0 + d_1\Delta T \quad (22)$$

with adjustable parameters a_i , b_i , c_i and d_i . The values of these quantities at $T = 75^\circ\text{C}$, i.e. in the close vicinity of the glass transition temperature, deviate from dependences (22). This may be explained by the fact that at a very small degree of supercooling ($\Delta T = 5\text{ K}$), the relaxation test was carried out at the strain ($\epsilon = 0.01$) that exceeded the yield strain. As a result, experimental data (curve 4 in Figure 1) demonstrate a combined effect of viscoelastic and viscoplastic deformations. This issue has been previously discussed in [7].

The parameters W and Σ increase with a decrease in temperature, which is in good agreement with an assumption about an increase in the ruggedness of the energy landscape with the growth of the degree of supercooling [34]. The initial Young modulus E_0 decreases with temperature in accord with conventional observations for the effect of temperature on elastic moduli. Surprisingly, the relaxation rate Γ decreases with temperature. This conclusion does not, however, contradict the theory of thermally activated processes, because the relaxation rate Γ is defined [see Eq. (3)] as the product of the attempt rate Γ_0 (which increases with temperature) by the factor $\exp[-\Omega(T)]$ that characterizes the ascent of the reference energy level at temperature T with respect to that at the glass transition temperature.

We now approximate experimental data in a tensile test with a constant strain rate $\dot{\epsilon}_0$,

$$\epsilon(t) = \begin{cases} 0, & t < 0, \\ \dot{\epsilon}_0 t, & t \geq 0. \end{cases} \quad (23)$$

For this purpose, we integrate Eqs. (14), (15), (19) and (20) with the material parameters W , Σ and Γ determined in relaxation tests and find the parameters g_0 and K_i which minimize deviations between results of numerical simulation and experimental data. Because the initial Young modulus E_0 found in relaxation tests underestimates stresses at the initial region of the stress-strain curve, the value of E_0 was found by fitting experimental data in the interval $\epsilon \in [0, 0.02]$.

First, we approximate the stress-strain curve at room temperature ($T = 25^\circ\text{C}$) obtained at the strain rate $\dot{\epsilon}_0 = 0.01 \text{ min}^{-1}$. The quantities K_i and g_0 are found by applying the steepest-descent procedure. Afterwards, we fix the parameters K_i and match experimental data at other temperatures and other strain rates with the only adjustable parameter g_0 . Figures 4 and 5 demonstrate good agreement between experimental data and results of numerical analysis. The initial threshold stress g_0 is plotted versus the strain rate $\dot{\epsilon}_0$ in Figure 6. This figure reveals that the dependence $g_0(\dot{\epsilon})$ is fairly well approximated by the function (conventionally used to describe the effect of strain rates on the yield stress)

$$g_0 = \beta_0 + \beta_1 \log \dot{\epsilon} \quad (24)$$

with adjustable parameters β_i .

We now repeat fitting experimental data for poly(methyl methacrylate) ($T_g = 105^\circ\text{C}$) at room temperature. Because of the lack of observations in relaxation tests and in tests with constant strain rates for the same specimens, we use experimental data in relaxation tests exposed in [35] (the relaxation master curve corresponding to various aging times after quench from 165°C) and experimental data in tests with constant strain rates measured in [36]. We begin with matching observations in tensile relaxation test (21) with the strain $\epsilon = 0.005$. Figure 7 demonstrates fair agreement between experimental data and results of numerical simulation. Using material parameters found in the relaxation test, we approximate observations in tests with constant strain rates. By analogy with the analysis of experimental data for polyurethane, we determine the coefficients K_i by fitting data in a test with the strain rate $\dot{\epsilon}_0 = 0.01 \text{ s}^{-1}$, fix their values, and match observations for other strain rates by using the only adjustable parameter g_0 . Figure 8 shows excellent agreement between experimental data and results of numerical analysis. The dependence $g_0(\dot{\epsilon})$ is depicted in Figure 6, which reveals the high level of accuracy of Eq. (24).

To assess the effect of temperature on the viscoelastoplastic response of poly(methyl methacrylate), we fit observations in relaxation tests (data are adopted from [37]) and in tests with a constant strain rate (measurements are taken from [16]) at various temperatures in the sub- T_g region. Figure 9 reveals good agreement between experimental data and results of numerical simulation. Because experimental data are available in a relatively small interval of time (3 decades), we reduce the number of adjustable parameters by setting $W = 0$ (which implies that only three constants are employed to match observations). The functions $\Sigma(T)$ and $\Gamma(T)$ are plotted in Figure 10, which demonstrates that the parameter Σ increases with the degree of supercooling (in agreement with results presented in Figure 2). The rate of relaxation Γ decreases with ΔT , in agreement with the theory of thermally activated processes. It is worth noting that the parameter Σ vanishes (the energy landscape becomes homogeneous) at the critical temperature $T_{\text{cr}} = T_g + 4.7 \text{ K}$, which is quite close to the critical temperatures for other

amorphous polymers, see [38]. The initial Young modulus E_0 is plotted versus temperature T in Figure 11. The dependence $E_0(\Delta T)$ is correctly described by Eq. (22), where the coefficient c_i take different values in the close vicinity of T_g , $\Delta T < 20$ K, and far below the glass transition point. Observations in tests with constant strain rates are depicted in Figure 12 together with results of numerical simulation (the initial Young modulus $E_0(T)$ was taken directly from the data in relaxation tests). This figure also reveals fair agreement between experimental data and the model's predictions. Material parameters g_0 and K_i for polyurethane and poly(methyl methacrylate) are listed in Table 1 which shows that these quantities have the same order of magnitude for the two polymers.

6 Concluding remarks

Constitutive equations have been derived for uniaxial isothermal response of glassy polymers at small strains. An amorphous polymer is treated as an ensemble of CRRs trapped in their cages. At low stress levels, relaxing regions are connected one with another, which ensures that macro-strain in a specimen coincides with the average micro-strain in a CRR. When the average stress exceeds some threshold level, links between CRRs break, and relaxing regions can slide one with respect to another (which induced viscoplastic deformation at the micro-level). Simple kinetic equations are proposed for changes in the threshold stress and plastic strain. The stress-strain relations are verified using experimental data for a polyurethane resin and poly(methyl methacrylate) at various temperatures and strain rates. Fair agreement is established between experimental data and results of numerical simulation.

Figure legends

1. The Young modulus E GPa versus time t s for polyurethane at temperature T °C. Circles: experimental data [33]. Solid lines: results of numerical simulation. Curve 1: $T = 25.0$; curve 2: $T = 35.0$; curve 3: $T = 50.0$; curve 4: $T = 75.0$
2. The dimensionless parameters W (unfilled circles) and Σ (filled circles) versus the degree of supercooling ΔT °C for polyurethane. Circles: treatment of observations [33]. Solid lines: approximation of the experimental data by Eq. (22). Curve 1: $a_0 = -12.8947$, $a_1 = 0.7053$; curve 2: $b_0 = -9.4737$, $b_1 = 0.4263$
3. The initial Young modulus E_0 GPa (unfilled circles) and the relaxation rate Γ s⁻¹ (filled circles) versus the degree of supercooling ΔT °C for polyurethane. Circles: treatment of observations [33]. Solid lines: approximation of the experimental data by Eq. (22). Curve 1: $c_0 = 1.8221$, $c_1 = 0.0100$; curve 2: $d_0 = -1.9310$, $d_1 = 0.0571$
4. Stress σ MPa versus strain ϵ for polyurethane loaded at temperature T °C with the strain rate $\dot{\epsilon}_0 = 0.01$ min⁻¹. Circles: experimental data [33]. Solid lines: results of numerical simulation. Curve 1: $T = 25.0$; curve 2: $T = 50.0$
5. Stress σ MPa versus strain ϵ for polyurethane loaded at $T = 25$ °C with the strain rate $\dot{\epsilon}_0$ min⁻¹. Circles: experimental data [33]. Solid lines: results of numerical simulation. Curve 1: $\dot{\epsilon}_0 = 0.1$; curve 2: $\dot{\epsilon}_0 = 0.01$; curve 3: $\dot{\epsilon}_0 = 0.005$
6. The initial threshold stress g_0 versus the rate of strain $\dot{\epsilon}_0$ min⁻¹ at $T = 25$ °C. Circles: treatment of observations for a polyurethane resin [33] and poly(methyl methacrylate) [36]. Solid line: approximation of the experimental data by Eq. (24). Curve 1: PU, $a_0 = 88.096$ and $a_1 = 13.448$; curve 2: PMMA, $a_0 = 97.922$ and $a_1 = 20.176$
7. The Young modulus E GPa versus time t s for poly(methyl methacrylate) at $T = 25$ °C. Circles: experimental data [35]. Solid line: results of numerical simulation with $W_0 = 12.4$, $\Sigma_0 = 14.8$, $E_0 = 2.0442$ GPa and $\Gamma = 0.05$ s⁻¹
8. Stress σ MPa versus strain ϵ for poly(methyl methacrylate) loaded at $T = 25$ °C with the strain rate $\dot{\epsilon}_0$ s⁻¹. Circles: experimental data [36]. Solid lines: results of numerical simulation. Curve 1: $\dot{\epsilon}_0 = 10^{-2}$; curve 2: $\dot{\epsilon}_0 = 5 \times 10^{-3}$; curve 3: $\dot{\epsilon}_0 = 10^{-3}$; curve 4: $\dot{\epsilon}_0 = 5 \times 10^{-4}$; curve 5: $\dot{\epsilon}_0 = 10^{-4}$
9. The Young modulus E GPa versus time t s for poly(methyl methacrylate) at temperature T °C. Circles: experimental data [37]. Solid lines: predictions of the model. Curve 1: $T = 50$; curve 2: $T = 75$; curve 3: $T = 85$; curve 4: $T = 90$; curve 5: $T = 100$
10. The dimensionless parameter Σ (unfilled circles) and the rate of relaxation Γ s⁻¹ (filled circles) versus the degree of supercooling T °C for poly(methyl methacrylate). Circles: treatment of observations [37]. Solid lines: approximation of the experimental data by Eq. (22). Curve 1: $b_0 = 3.4931$, $b_1 = 0.7483$; curve 2: $d_0 = 1.0853$, $d_1 = -0.0564$
11. The initial Young modulus E_0 GPa versus the degree of supercooling ΔT °C for poly(methyl methacrylate). Circles: treatment of observations [37]. Solid lines: approximation of the experimental data by Eq. (22). Curve 1: $c_0 = 0.3217$, $c_1 = 0.0504$; curve 2: $c_0 = 1.1763$, $c_1 = 0.0069$

12. Stress σ MPa versus strain ϵ for poly(methyl methacrylate) loaded at temperature T °C with the strain rate $\dot{\epsilon}_0 = 0.1 \text{ min}^{-1}$. Circles: experimental data [16]. Solid lines: results of numerical simulation. Curve 1: $T = 50$; curve 2: $T = 75$

Table 1: Adjustable parameters g_0 and K_i for polyurethane and poly(methyl methacrylate)

Material	T °C	g_0 MPa	K_1 MPa $^{-1}$	K_2 MPa $^{-1}$	K_3 min $^{-1}$
PU	50.0	64.0	0.02	0.8	35.0
PU	75.0	38.0	0.02	0.8	35.0
PMMA	50.0	36.0	0.07	1.0	20.0
PMMA	75.0	32.5	0.07	1.0	20.0
